ABSTRACT

To survey high-volume hip arthroscopists regarding their current indications for labral reconstruction, graft preference and technique. In May 2018, a cross-sectional based survey was conducted on high-volume hip arthroscopists. A high-volume surgeon was defined as an orthopaedist who had case experience ranging from 50 to 5000 hip arthroscopies performed annually. The survey included their current indications for labral reconstruction, graft preference and technique. Twelve high-volume surgeons successfully completed the questionnaire. The mean arthroscopic procedures performed by the surgeons annually was 188.7 (range 60–350). Four surgeons (33.3%) performed <5 labral reconstruction cases per year, three (25.0%) 5–10 cases per year, two (16.7%) 11–15 cases per year and three (25.0%) over 20 cases per year. Of the 12 surgeons, 11 (91.6%) would reconstruct in certain primary settings and 100% would reconstruct in revision settings. In the primary setting, the main indications for reconstruction were poor quality labral tissue, calcified labrum and hypoplastic labrum. None of the surgeons recommended labral reconstruction for reparable labral tears in primary cases. In primary cases of irreparable labra, 58.3% of the surgeons favoured reconstruction over debridement. In revisions, 100% of the surgeon favoured reconstruction over debridement; 91.7% chose an allograft option versus an autograft alternative. Amongst high-volume arthroscopists, labral reconstruction was considered a valuable technique to restore labral function. Labral reconstruction was more often advocated in revision than in primary settings. Allograft was the preferred choice for reconstruction. Excision of the labral tissue prior to reconstruction was favoured over augmentation. Fewer surgeons performed circumferential reconstruction than segmental reconstruction.

INTRODUCTION

The labrum is a vital structure for normal biomechanics of the hip joint [1–6]. Preservation and restoration of labral function have been advocated as key factors for success in hip preservation surgery. Several publications demonstrated that hip arthroscopy is a valid tool to accomplish these goals [7–12]. Labral repair versus debridement may lead to better results in the short- and mid-long-term outcomes especially in a high-risk population like ‘borderline’ dysplastic patients [8, 13–19]. The modernization and explosion of innovative hip arthroscopy tools and techniques have shifted the field towards labral preservation procedures over simple debridement [14, 20]. Nevertheless, in circumstances when labral tears cannot be repaired (Fig. 1), and labral reconstruction is an alternative technique to re-establish labral functionality [21–23]. Different authors have published early outcomes that affirm reconstruction’s utility [23–26]. However, the ideal technique, the optimal graft and even proper indications for procedure remain subjects of debate [22, 27–31]. Both, autograft and allograft have been used for labral reconstruction [22], going from iliotibial band [32, 33], indirect head of the rectus femoris [21] and hamstring autografts [26], to iliotibial band [25, 30, 34] and hamstring allografts [31, 35]. Technically demanding, labral reconstructions currently can only be accomplished reproducibly by a handful of
orthopaedic hip surgeons around the world [22, 30, 36–39]. The purpose of this study was to survey these high-volume hip arthroscopists to document their current indications for labral reconstruction, technique and graft preference (allograft versus autograft) [31, 32, 35, 38]. It was hypothesized that labral reconstruction in the setting of irreparable tears would be an important resource of treatment among high-volume hip specialist orthopaedic surgeons.

MATERIALS AND METHODS
In May 2018, a cross-sectional based survey questionnaire was conducted on hip specialist orthopaedic surgeons classified as ‘high-volume surgeons’ who served as faculty members during a Hip Arthroscopy Current Concepts meeting [40–43]. Based on previous high-volume hip arthroscopy surgeon consensus, high volume was defined as an orthopaedic surgeon who had case experience ranging from 50 to 5000 hip arthroscopies performed annually [43, 44]. The questionnaire itself was not a validated questionnaire. Rather it represented a list of commonly debated questions within the hip arthroscopy community concerning arthroscopic labral reconstruction. The survey included four fill in the blank questions, six single-choice questions and two multiple-choice questions (Appendix). The participants completed their surveys in person, and responses were kept anonymous. Questions were designed to include each respondent’s current indications, graft type preference and technique for labral reconstruction.

The study was exempt from institutional review board because of the confidential and anonymous nature of the survey. Consent from each individual surgeon was obtained before participation. The lead and senior authors (D.R.M. and B.G.D.) developed the current study in consultation with the Institution Statistics Department. Because the current study only represented the prevalence of reconstruction among high-volume practices, statisticians agreed that statistical analysis would not be appropriate for the study’s purposes.

RESULTS
Arthroscopic labral reconstruction as an option
In total, 21 high-volume hip specialist orthopaedic surgeons were present at the meeting and invited to participate in the consensus, and 13 surgeons responded to the questionnaire. Of the 13, 12 (92.3%) had labral reconstructions in their surgical repertoire. High-volume surgeons that did not include labral reconstruction in their current practice were excluded from the study. The mean total number of hip arthroscopies performed by the surgeons annually was 188.7 (range 60–350).

Arthroscopic labral reconstructions performed annually
Each surgeon was asked to report the average number of labral reconstructions they performed per year. Responses indicated 33.3% of the surgeons performed <5 reconstructions per year, 25% between 5 and 10, 16.7% between 11 and 15 and 25% performed 20 or more.

Labral reconstruction in primary hip arthroscopy
Percentages of labral reconstructions in the primary setting were collected. All but one of the surgeons (91.7%) performed reconstruction in <5% of primary cases (Table I).

Labral reconstruction in revision hip arthroscopy
Surgeons reported the occurrence of labral reconstruction in the revision setting. In total, 33.3% of the surgeons reported encountering 5–10 cases of reconstruction in such setting, 25% reported 11–20 cases, 33.3% reported 21–40 cases and 8.3% reported 41 or more cases per year, (Table I).

Indications for labral reconstruction
The following were selected as indications for labral reconstruction in a primary case: poor quality labral tissue (21.1%), calcified labrum (26.3%) and hypoplastic labrum (7.9%). No surgeon selected ‘torn labrum’ as an indication for labral reconstruction (Table II).

Revision arthroscopy for failed prior labral repair or prior reconstruction was another selection for indications for labral reconstruction (26.3% and 18.4%, respectively) (Table II).
Labral reconstruction versus labral debridement in primary and revision surgery

In primary cases, 58.3% of the surgeons selected labral reconstruction over debridement for hips with irreparable labral tear findings. In revision cases, all surgeons agreed to proceed with reconstruction. In cases of failure of prior labral reconstruction, 63.6% of the surgeons would perform a new reconstruction, while 36.4% would abstain (Table II).

Graft preference and technique for labral reconstruction

For graft choice, 91.7% of the surgeons selected some form of allograft for labral reconstruction (Table III). For treatment of the pre-existing labral tissue prior to reconstruction, 54.5% selected complete excision, while 45.5% selected incorporation of native labral tissue into the reconstruction (augmentation). Segmental reconstruction was the preferred technique over circumferential (50% and 16.7%, respectively; Table III).

DISCUSSION

The present study reports current trends in hip labral reconstruction among high-volume hip specialist orthopaedic surgeons. Labral reconstruction was found to be a common procedure for labral function restoration for high-volume hip specialist orthopaedic surgeons; 92.3% of the surveyed surgeons reported having this technique in their arsenal. Arthroscopic reconstruction is a technically demanding procedure that requires long and high-volume training before adequate adroitness. As such, it is unlikely that the presented outcomes reflect reconstruction rates in lower-volume surgeons who may not be able to reproducibly achieve the same results [22, 27, 36, 45, 46].
Recently, Mehta et al. [45] published findings regarding the learning curve in hip arthroscopy. According to the authors, a surgeon could be classified as low-volume, medium-volume, high-volume or very high-volume arthroscopist. Surprisingly, just to be considered a low-risk surgeon (very high volume), one had to perform at least 519 hip arthroscopies within 5 years. The authors concluded that ‘the learning curve for hip arthroscopy was unexpectedly demanding’. In the current study, even within the cohort of high-volume surgeons, there was a wide variation in annual reconstructions performed. White et al. [27, 47] highlighted the possibility of being an ‘experienced hip arthroscopist’, yet a ‘novice labral reconstructi”
with reconstruction. It seems that the current consensus is to ‘save’ the labrum with repair when possible [52].

Multiple graft options for reconstruction have been proposed [30–32, 34, 35]. Early techniques used autografts, while recent procedures have shifted towards allografts [43, 48]. Advantages and disadvantages of autografts and allografts have been described, but presently there is a dearth of available information regarding the type of graft for reconstruction and the influence this choice may have in patient outcomes or hip survivorship [14, 22, 46, 53]. In total, 91.7% of the surgeons surveyed chose an allograft option over an autograft alternative. The risk of donor site morbidity and possible reduction of surgical time may explain these decisions.

Different labral reconstruction techniques have been described [30, 31, 34, 54]. Currently, segmental and lately circumferential reconstructions are in vogue (Fig. 2). In general, the segmental technique reconstructs only the non-reparable ‘segment’ of the labrum (Fig. 3) [26, 33, 35]. On the other hand, circumferential reconstruction does not require precise measurement of the labral defect, and proceeds in a ‘front-to-back’ fashion [27, 30, 31]. Both techniques have shown good results in short-term follow-ups and neither has proven to be superior [26, 30]. The 50% of high-volume surgeons chose segmental reconstruction, 16.7% selected circumferential reconstruction and 33.3% a combination thereof.

Incorporation of the remaining labral tissue prior to reconstruction, known as augmentation, has been proposed [54]. Almost half of the surveyed surgeons selected this approach.

**Limitations**

Limitations of this study must be acknowledged. First, the questionnaire used for survey purposes was not a validated one. Second, the questionnaire itself included questions that are controversial among hip specialist orthopaedic surgeons and did not record quantitative outcome measures. Third, this study presents opinions and the expertise of high-volume specialized orthopaedic hip surgeons and did not record quantitative outcome measures. Fourth, specific trends related to graft selection based on the surgeons’ geographic area was not taken into account. Fifth, though based on previous publications, the number of performed cases selected to defined a high-volume hip arthroscopy surgeon and high-volume labral reconstructionist, were arbitrary and needs validation [36].
CONCLUSIONS
Amongst high-volume arthroscopists, labral reconstruction was considered a valuable technique to restore labral function. Labral reconstruction was more often advocated in revision than in primary settings. Allograft was the preferred choice for reconstruction. Excision of the labral tissue prior to reconstruction was favoured over augmentation, and segmental reconstruction was also favoured over the circumferential technique.

FUNDING
This study was performed at and received funding from the American Hip Institute. No specific grant was given for this study. This study was approved by the Institutional Review Board (IRB ID: 5276).
